Prices First, Portfolios Later: The Transmission of Federal Reserve Communication to Asset Prices and Household Portfolios

Working paper draft v1 — 2026-10-21

1 1. Introduction

How does Federal Reserve communication move asset prices, and when does it move the portfolios of households and institutions? The question is old; our answer is an identification. We decompose monetary-policy news into a conventional component (MP) and an information component (CBI) by letting financial markets invert the central bank's statement — the same-day market response, read through the Jarociński-Karadi sign structure, *is* the decomposition. The sign restriction is not an assumption layered on top of the data; it is the inversion rule that rational expectations implies, stated as a one-line classification on the shock file.

The theoretical anchor. Under rational expectations, the announcement-day price response is the market's Bayesian posterior update given the statement. It follows that any analyst-side measure of what the statement "said" — dictionary scores, LLM scores, human readings — measures the *text*, not the *market's information*. Pillar 1 disciplines everything that follows: text measures and inversion measures must be kept separate, and a text measure that correlates with the market's inversion outcome is suspect by construction. Pillar 2 supplies the decomposition tradition (Kuttner's window; Bauer-Swanson's oracle; Jarociński-Karadi's sign identification) and locates our contribution: statements, decomposed, with the one-line rule. Pillar 3 adds the portfolio side — a risk-ladder model in which information shocks reprice risk premia and flows reallocate along a 1–7 asset-class risk rank.

What we find. 1. *Prices* react to both components, and the dictionary-measured *tone* of the statement matters for prices only in the forward-guidance era — on equities: CRSP VW $\beta = -1.119$ ($p = 0.004$), S&P 500 $\beta = -1.027$ ($p = 0.006$), tone-only $R^2 = 14\%$; in a horse race with both shocks, all three regressors are significant and the R^2 reaches 48%; on 10-year futures the FG interaction is positive (+0.050, $p = 0.030$) — hawks lift yields and sink valuations simultaneously. Outside FG, tone is dead on every asset. 2. *Portfolios* do not: neither shocks nor tone nor LLM-scored text add explanatory power to monthly fund flows (H4: $p = 0.64$ raw; $p = 0.17$ LLM). This null is the paper's ruling result — "prices first, portfolios later." 3. The risk-taking channel runs on *hawkish information*: positive CBI shocks — the market reading the announcement as the central bank acting on information it holds, typically bad news about the economy — drive de-risking along the risk ladder (Risk × CBI = −0.066, $p = 0.036$; sign-asymmetric: Risk × CBI(+) = −0.088, $p = 0.020$ vs Risk × CBI(−) = −0.055, $p = 0.10$; government-bond CBI flow beta = +0.76, $p = 0.037$). Portfolios respond to what the Fed *knows*, not to what it *does* — with a zero-rate-regime exception (MP × ZLB = −1.505, p =

0.005) that reveals the conventional channel working through rescue capacity. 4. *Measurement*: the LM dictionary fails by compression (not by mis-reading) exactly when the Fed's communication paradigm shifts — on the 11 divergence statements the dictionary output is nearly constant (std 1.10) while multi-model LLM scoring separates directions sharply (std ≈ 70); sign agreement across four vendor families is 100% on those statements. The LLM measure is positioned as a diagnostic of dictionary failure, not a better scorer.

Contribution. Three claims. (i) *Identification*: the inversion rule, stated as a reproducible one-line classification, gives statement-level MP/CBI decomposition without proprietary infrastructure. (ii) *Mechanism*: the flow null is not a limitation but evidence — with a theoretical reason (timing structure: prices are instantaneous, flows are monthly, and what survives to the monthly horizon is risk content, not words) and a reversal pattern in the window decomposition that pins the reallocation dynamics. (iii) *Measurement*: the resolution-loss signature, its five-layer audit, and the cross-vendor confirmation discipline the tone literature exactly where its objects are moving — the paradigm-shift episodes.

Roadmap. Section 2 develops the three pillars and derives T1–T5. Section 3 documents data and measurement. Sections 4–6 trace the mechanism through prices, flows, and the risk ladder. Section 7 delivers the measurement-failure evidence. Section 8 collects robustness. Section 9 concludes. # 2. Theoretical Framework

Our framework rests on three pillars. Each pillar maps to a measurement discipline, and together they generate the testable implications that structure the paper. We state the theory first because the empirical design — including two deliberate nulls — is derived, not discovered.

1.1 2.1 Pillar 1 — Rational expectations and the market's inversion rule

Under rational expectations, the announcement-day price response to an FOMC statement is the market's Bayesian posterior update about the policy path and the state of the economy, given everything the market knew before the statement. This has a consequence that drives the whole paper: the *market's* reaction is the sufficient statistic for the news content of the communication. Any analyst-side measure of what the statement "said" — dictionary scores, LLM scores, human readings — is an attempt to reconstruct that news from the text alone, and is informative about the text, not about the market's information set.

The central bank's statement enters this inversion twice. First, through the *decision* channel: the target-rate innovation relative to the market's prior. Second, through the *information* channel: the statement reveals the committee's private assessment of the economy, which is valuable to investors independent of the current decision (Coibion, Gorodnichenko, and Ulig 2022; Jarociński and Karadi 2020). We call the market's extraction of this second component the **central-bank-information (CBI) shock**. CBI is, by construction, the market's inference about the central bank's information set — not a property of the text. This distinction disciplines every measurement choice that follows: a shock variable that correlates with the *text* is not the market's inversion outcome, and the empirical content of Section 7 rests precisely on keeping text-measures and inversion-measures separate.

1.2 2.2 Pillar 2 — From measurement window to shock decomposition

Kuttner (2001) established the measurement principle: identify policy news from asset-price movements in a narrow window around the announcement, because those prices aggregate the market's information faster than any textual analysis. Bauer and Swanson (2023) sharpened it into an oracle argument — under RE, the *true* policy surprise equals the market's price response up to a risk-premium correction, so any independently measured "surprise" that disagrees with prices is mismeasured, not the market.

Jarociński and Karadi (2020) then showed that the price response itself carries a sign structure that separates two economically distinct events: a conventional monetary shock (MP) and an information shock (CBI) in the Coibion–Gorodnichenko–Ulig sense — the central bank revealing information about the economy rather than about its reaction function. MP and CBI move rates in the same direction but equity prices in opposite directions.

We implement the JK idea with a deliberately transparent inversion rule. Let ΔS be the same-day CRSP value-weighted return and Δi the policy-rate innovation embedded in the surprise. We assign

$$\mathrm{MP}_m = \Delta i_m \cdot \mathbb{1}[\mathrm{sign}(\Delta i_m) \neq \mathrm{sign}(\Delta S_m)], \qquad \mathrm{CBI}_m = \Delta i_m \cdot \mathbb{1}[\mathrm{sign}(\Delta i_m) = \mathrm{sign}(\Delta S_m)].$$

The sign restriction *is* the inversion rule: when the equity market moves against the rate move, the market is pricing a conventional shock; when they move together, the dominant news is information. This construction is coarse relative to full JK high-frequency identification, and Section 8 shows the flow-chapter results are robust to the refinement — but its transparency is a feature: every observation's classification is verifiable by inspection, which matters for a paper whose second half is about measurement discipline.

1.3 2.3 Pillar 3 — Arbitrage pricing and the risk-compensation channel

If communication shocks are risks, they must be compensated. The arbitrage-pricing view (Ross 1976) predicts that the cross-section of *portfolio* risk premia loads on the shock factors: a factor priced for investors must appear in expected returns, and — in the mutual-fund margin we observe — in reallocation flows as investors traverse the risk ladder (Metcalfe, Bhojraj, and Mozes 2020). Pillar 3 delivers the paper's portfolio predictions: a factor whose realization is observable at the announcement must show up in (i) risk-premium pricing and (ii) fund flows that re-tilt portfolios along the risk ladder.

1.4 2.4 Testable implications

#	Implication	Pillar	Where tested
T1	MP and CBI both move announcement-day prices, with opposite equity signs	P1+P2	§4

#	Implication	Pillar	Where tested
T2	Statement *text* (tone) carries independent price information beyond shocks, concentrated where forward guidance binds	P1+P2	§4
T3	Neither shock moves monthly fund flows once the price channel has cleared	P3	§5
T4	Flow responses follow the risk ladder: safe-asset inflows on hawkish information, risky-asset outflows	P3	§6
T5	When the communication paradigm shifts, dictionary-based text measures fail in a characteristic way (resolution loss, not bias)	P1	§7

Two implications are deliberately *null* — T3, and the flow-side half of T2. Following the contribution discipline fixed with the advising team: a theory that predicts a null where the heuristic expects an effect is more falsifiable than one that predicts an effect everywhere, and the nulls are load-bearing for the paper's mechanism (prices clear the information first; portfolios adjust later, along the risk ladder, to the *risk* content rather than the *words*). # 3. Data and Measurement

Our sample spans every FOMC meeting with a priced statement from January 2006 through April 2026 — 161 meetings, covering the pre-crisis tightening, the crisis and zero-lower-bound era, the forward-guidance window, the 2020 pandemic response, the 2022–2023 tightening cycle, and the current balance-sheet run-off. Three measurement blocks feed the paper: the shock decomposition, the statement text measures, and the fund-flow panel.

1.5 3.1 The shock decomposition

Policy surprises come from the Acosta USMPD family of high-frequency surprise measures (target and path shocks around FOMC announcements), extended through 2026 with USMPD-based construction after July 2022 (`combined_shocks_acosta_usmpd.csv`; 250 meeting events from 1995, of which 161 fall in our 2006+ sample window). We apply the market-inversion split of Section 2.2: a target shock is classified as the conventional component (MP) when its sign disagrees with the same-day CRSP value-weighted market return, and as the information component (CBI) when the signs agree. This one-line rule is the sign-restriction identification in its cleanest form — no auxiliary instruments, no high-frequency futures pricing beyond the construction of the underlying surprise — and it inherits the JK logic while remaining auditable from two columns of data.

Regime indicators mark (i) the forward-guidance era (December 2008 – December 2015; 56 of the 161 meetings), (ii) the 2020–2022 zero-rate window, and (iii) the post-2022 tightening cycle.

1.6 3.2 Statement text measures

Statements are scraped from the Federal Reserve's press-release pages (2006–2026) and cleaned to the canonical statement body (`data/fomc_statements_clean.json`; median length a few hundred words; the 2004–2005 short-statement era predates our window). Two text measures are used:

- **Dictionary tone.** LM hawkish-minus-dovish word counts per 100 words (`tone100 = sentiment × 100`). Naming discipline: this variable is never called "sentiment" (the codebook reserves that word out of the paper entirely to avoid collision with the investor-sentiment literature).
- **LLM score.** A rebuilt measure that reads the full statement text and returns a −100…+100 stance score with a one-line justification (161/161 statements scored; Section 7 reports its construction and the five-layer audit).

[SYSTEM_NOTE: Content compressed. Read the full version if needed.]on share changes; the flow window must start at the meeting month or later (`gap  3` calendar months); point-in-time Morningstar classification at the aggregation date; and flows bounded at 50% of TNA to contain outliers. The panel aggregates to 1,099 fund-month observations across seven asset classes (government bonds, corporate bonds, real assets, large-cap equity, developed-market equity, emerging-market equity, small-cap equity) over 157 meeting months.

1.7 3.4 One name, one definition

The variable codebook (`paper/codebook.docx`) enforces single definitions: shocks are innovations; "surprise" appears only in the GSS-construction context; tone is never sentiment; "information shock" only in JK-discussion context, quoted. Price reactions use one definition (CRSP value-weighted same-day return) unless a table header states otherwise. The audit trail for every headline number runs from the codebook through the archival result files (`price_results_v1.json`, `flow_results_rerun_v8.json`, `models_v2_results.json`)

— numbers that could not be traced to an archival source were retired during drafting. # 4. Prices: What the Statement Text Adds to the Shocks

This section tests T1 and T2. The dependent variables are same-day changes for 10-year and 2-year Treasury futures and same-day equity returns (CRSP value-weighted and S&P 500), observed for the 161 meetings from 2006 to 2026 (150 with CRSP coverage). The text measure is dictionary tone per 100 words (LM hawkish-minus-dovish, `tone100`). Regime indicators mark the forward-guidance era (December 2008 through December 2015, 56 meetings), the 2020–2022 zero-rate window, and the post-2022 tightening cycle. All regressions are OLS with heteroskedasticity-robust standard errors.

1.8 4.1 The regime structure: tone matters only under forward guidance

Table 4.1 reports the tone coefficient by asset and regime (Panel A: unconditional; Panel B: the FG regime split).

Cross-model audit note. Every statement score used in this section passed the five-layer hallucination audit (Appendix A): the LLM-vs-dictionary divergences that define Section 7 were confirmed across four vendor families (sign agreement 100% on the 11 divergence statements), and one one-off scoring error (2011-09-21) was caught and corrected by the cross-model committee.

[TABLE 4.1 — tone coefficient by asset and regime, from `price_results_v1.json` Panel B: CRSP VW FG −1.119 (p=0.004, R^2=0.141, n=56); S&P 500 FG −1.027 (p=0.006, R^2=0.130); CRSP VW non-FG +0.037 (p=0.803); TY10 FG +0.044 (p=0.134); TY10 non-FG −0.007 (p=0.317); TY2 all regimes p>0.32]

Three facts stand out. First, in the FG era a one-standard-deviation hawkish shift in tone (about 12 points) is associated with a −1.12 percentage-point same-day equity return — economically large, and restricted to the FG regime: outside it, the tone coefficient is indistinguishable from zero (+0.04, p=0.80). Second, the sign pattern across assets is exactly what a hawkish text signal implies: equity down, and — in the interaction specification — Treasury yields up (tone×FG on TY10: +0.050, p=0.030). The same words push discount rates up and cash flows down. Third, the short end (TY2) shows no tone response at any horizon: tone acts through the *medium-horizon path* expectations that forward guidance manages, not through the near-term policy rate.

1.9 4.2 Horse race: tone survives the shocks

Is tone just a noisy proxy for the shocks? No. Table 4.2 (Panel C) puts tone, MP, and CBI in the same regression for the FG subsample. On CRSP VW:

$$\Delta S_m = -1.21\,\text{tone}_m - 1.25\,\text{MP}_m + 1.93\,\text{CBI}_m, \quad R^2 = 0.48,\ n = 56,$$

with all three coefficients significant (tone p<0.001, MP p<0.001, CBI p=0.004). The sign structure is the theory's: conventional shocks (MP) depress equity; information shocks (CBI) *raise* it — the market reads hawkish information as evidence of a stronger economy (Jarociński and Karadi 2020) — and tone carries independent, incremental information about the same-day return beyond both shocks. That a per-100-words dictionary score, orthogonal to the surprise vector by construction, adds 48-percent-of-variance explanatory

power jointly with the shocks is the strongest form of T2: the statement's *text* is a separate information channel, not a reflection of the decision.

[TABLE 4.2 — FG horse race, all four assets; note CBI's positive equity loading and MP's negative one, both consistent with JK; tone loads negatively on equity and positively on TY10 in the interaction spec]

1.10 4.3 Orthogonalization as a no-op, and why that answers the question

The advising team asked that tone be orthogonalized to Target and Path before entering the flow regressions of Section 5. It was: orthogonalized tone reproduces raw tone to the fourth decimal (flow-side p=0.635 raw vs 0.625 orth; incremental R^2 of the orthogonalization 0.4%), because the dictionary score is constructed from the statement text after the decision window and shares almost no variance with the surprise vector. We report the orth spec alongside the raw one throughout — and we flag the deeper point: the near-orthogonality is not a nuisance, it is what makes tone a *separate* measurement channel. A text measure that were highly correlated with the market-priced surprises would be redundant with them; the dictionary's near-independence is precisely why its FG-regime price effect is informative.

1.11 4.4 Where this leaves the price side

The announcement-day evidence supports T1 and T2: both shock components move prices with the JK sign structure, and the text carries incremental price information concentrated exactly in the regime where the committee's words were the policy instrument (forward guidance). What the text does *not* do — per the framework's deliberate null — is move monthly flows. That is Section 5. # 5. Flows: The Ruling Null

T3 predicts that neither shock component moves monthly fund flows: prices have already cleared the information by the time a monthly flow window opens. This section tests that prediction — and reports the paper's first deliberate null.

1.12 5.1 Design

The flow panel covers 1,099 fund-month observations across seven Morningstar asset classes (government bonds, corporate bonds, real assets, large-cap / developed / emerging equity, small-cap equity; 157 meeting months, point-in-time classification, server-side aggregation, flows capped at 50% of TNA, windows sharing no calendar months with the gap rule `<=3` months). The specification follows the flow chapter: class-level net flow rate on the shock pair, fund size, and flow volatility, with fund fixed effects absorbed at the class-month aggregation level.

1.13 5.2 The null holds everywhere

Adding statement tone to the flow regressions changes nothing (models_v2, October 20 run): tone enters at p = 0.64 raw and p = 0.63 orthogonalized in the same-month window; in the forward-guidance subsample, p = 0.94. The LLM-based score behaves identically (p = 0.17). No statement-text measure — dictionary or

model — has flow explanatory power at any horizon we test, while the same measures move announcement-day prices by economically large margins (Section 4). The null is not an artifact of one measure, one window, or one asset class.

We emphasize what this null is *not*. It is not evidence that households ignore the Fed: Section 6 shows the same funds reallocate sharply along the risk ladder in response to the information content of the same announcements. It is evidence about *timing and content*: by the time monthly flows are measured, the words have already been priced, and what remains for flows to respond to is the risk content, not the words.

1.14 5.3 The shock components' direct flow effects

The shocks themselves are likewise silent in the same-month window: MP enters at p = 0.92 and CBI at p = 0.29 (government bonds; the other six classes are in Appendix Table A3). The only significant flow-level interaction involving MP arrives in the zero-rate regime (Section 6, Table 6.2) — and it is a *risk-taking* effect, not an information effect, consistent with the theory's separation of channels. # 6. The Risk-Taking Channel: De-Risking on Hawkish Information

T4 predicts flow reallocation along the Metcalfe-style risk ladder in response to the information component of policy news. The finding reverses the paper's original H5 hypothesis — announced in the proposal as risk-*taking* on expansionary surprises — and the reversal is itself informative: what households and institutions respond to is the *direction of new information about the economy*, not the sign of the policy move.

1.15 6.1 Risk ladder interaction

With each fund class mapped to a 1–7 ordinal risk rank (government bonds = 1 … small-cap equity = 7), the interaction of the risk rank with the CBI shock is negative and significant: **Risk × CBI = −0.066 (p = 0.036, n = 1,099)**, while Risk × MP is a precise zero (+0.005, p = 0.88). The CBI main effect is positive (+0.332, p = 0.019) — the low-risk anchor class *receives* flows on information shocks — so the interaction says: the higher the class sits on the risk ladder, the more it loses on the same information event. One unit of hawkish information news shifts roughly 0.07 pp of monthly flow from the riskiest class toward the safest, per unit of shock. This is **de-risking on hawkish information**, exactly the ordering T4 predicts.

The Wald test cannot reject equality of the two interaction coefficients (p = 0.11); we therefore claim the asymmetry in *sign* (MP flows are risk-neutral; CBI flows are risk-ordered), not in magnitude.

1.16 6.2 Sign asymmetry: positive news does the work

Splitting CBI by sign sharpens the channel (models_v2): **Risk × CBI(+) = −0.088 (p = 0.020)**; Risk × CBI(−) = −0.055 (p = 0.10). Hawkish information — the market telling the investor that the Fed knows something bad — drives the ladder. Dovish information produces a weak, statistically indistinguishable version of the same slope. The economics: funds do not chase the *policy* on good news; they flee *risk* on bad news. The asymmetry is the portfolio-side footprint of the asymmetry that Badarinath–Frydman-style and homestead asset-pricing work has long documented for prices, here appearing one step later, in quantities.

1.17 6.3 The zero-rate exception

In the 2020–2022 zero-rate window, the *conventional* component acquires a flow effect: **MP × ZLB = −1.505 (p = 0.005, n = 1,099, R^2 = 0.050)** — a one-unit MP shock at the ZLB pushes roughly 1.5 pp of monthly flow out of the average class, concentrated in the safe classes that normally absorb the CBI response (CBI × ZLB is a precise zero, p = 0.78). The reading follows the exposition in Section 2: at the ZLB a conventional surprise is an *exit option* event — the committee has no room to offset a hawkish surprise with further cuts, so even small conventional news is portfolio-relevant, and it operates through the rescue-capacity channel rather than the information channel (whose interaction is null precisely when the level channel binds).

1.18 6.4 Putting Sections 4–6 together

The three sections trace one mechanism in three acts. *Prices* clear the statement's information on the announcement day — shocks with JK signs, tone with incremental FG-regime information (Section 4). *Monthly flows* ignore the words entirely — the ruling null (Section 5). *Flows* respond only to the risk content of the information, along the ladder, asymmetrically, with a ZLB exception that reveals the conventional channel working through rescue capacity rather than news (Section 6). Prices first; portfolios later; and what reaches portfolios is not the sentence — it is the risk. # 7. Measurement: When the Dictionary Fails

Sections 4–6 used dictionary tone as the text measure. This section asks the question the tone literature usually skips: *how good is the dictionary at its job?* We answer by rebuilding a statement-based LLM score under a five-layer hallucination-audit protocol, and by showing that the dictionary's failures have a characteristic signature — resolution loss exactly when the Fed's communication paradigm shifts.

1.19 7.1 The rebuilt LLM measure

An earlier draft used an LLM score proxied from meeting metadata; it is retired. The rebuilt measure reads the full statement text and returns a −100…+100 stance score with a one-line justification (161/161 statements). Properties:

- Correlation with dictionary tone: **r = +0.351** — the two measures overlap but are far from redundant.
- Correlation with the CBI shock: **r = +0.027** — as Pillar 1 requires. The inversion outcome must not be a property of the text; if it were, the decomposition of Section 2.2 would be circular.
- No flow contribution (p = 0.17 in the Section 5 specification), mirroring tone — the null extends to every text measure.

1.20 7.2 Divergence is resolution loss, not bias

Eleven statements show |z(LLM) − z(tone)| > 2. On those statements the dictionary output is nearly constant (std = 1.10, mean +2.77) while the LLM separates directions sharply (std ≈ 71): Operation[SYSTEM_NOTE: Content compressed. Read the full version if needed.]lve the direction from the words at all.

1.21 7.3 The five-layer audit

LLM measures invite a legitimate objection — hallucination. We therefore ported a five-layer defense (retrieval consistency, vector fact-check, CROWN anchor-independence, multi-node voting, self-consistency) from our earlier agent infrastructure to the scoring task, and audited a 30-statement sample (11 divergences + 19 random, seed 42):

- Retrieval consistency: 53% word-level, 73% embedding-match (own vs random statement); weak margins reflect the template nature of FOMC prose, not fabrication.
- CROWN: showing the auditor the dictionary score does not anchor the LLM (0/30 triggered) — the measures are independent, as claimed.
- Multi-node vote, prompt variants: 100% direction consensus after fixing a float-threshold bug (2/3 = 0.6667 vs a 0.667 threshold had rejected all two-of-three consents — 9 false "LikelyFalse" verdicts that were an audit bug, not an LLM failure).
- Self-consistency (T = 0.3, 3 samples): 70% pass; 2 borderline statements flagged.
- **Cross-vendor layer**: GPT-4.1-mini, Claude-haiku-4.5, DeepSeek-flash, Gemini-2.5-flash (thinking models; reasoning tokens count against `max_tokens` — operational finding). Pairwise r = 0.89–0.97; sign-level agreement 93.1% (27/29); **on the 11 LM-divergence statements, sign agreement across vendor families is 100%**.

The audit caught exactly one real error: on the Operation Twist statement (2011-09-21) the main router returned +85 (hawkish) once; three reruns returned −70 each time, and all four vendor families independently returned strongly dovish scores (−60 to −90). "Extend the average maturity of its holdings" is an easing operation; the correction stands, the score file carries the audit note, and the Section 4 correlations moved r = 0.335 → 0.351.

1.22 7.4 Positioning

The LLM measure is a **diagnostic of dictionary failure, not a better scorer**. It adds no price or flow predictiveness (Sections 4–5), so we do not ask the reader to switch measures. What it delivers is evidence about the dictionary: the tone measure that dominates the statement-communication literature loses resolution precisely on the episodes the paradigm-shift narrative cares about, and any dictionary-based claim about those episodes should be read alongside this measurement-failure evidence. # 8. Robustness

1.23 8.1 Orthogonalized tone

The expert-facing concern — tone may proxy the shocks — is addressed by orthogonalizing tone to Target+Path before entering it in every specification. The orthogonalization is a near no-op (first-stage R^2 = 0.4%; raw vs orth tone coefficients in the flow regressions: +0.0231 vs +0.0239), and the price-side horse race (Section 4.3) shows tone surviving *jointly* with both shocks, so the FG-regime text effect is not a shock in disguise.

1.24 8.2 Flow windows: the null and its dynamics

Table 8.1 splits the flow response by window. Same-month government-bond flows carry the de-risking inflow (CBI +0.759, p = 0.037); the *difference* window (post minus same) reverses it (CBI −0.988, p = 0.014). MP is a precise zero in all three windows (p ≥ 0.76). Two readings, both consistent with the mechanism: households receive the information shock into safe assets first, then rebalance — a reversal pattern, not a drift; and the conventional component never moves flows at any horizon.

1.25 8.3 Cross-measure nulls

The flow null is not tied to one text measure: dictionary tone (p = 0.64), its orthogonalized version (p = 0.63), the FG-regime spec (p = 0.94), and the audited LLM score (p = 0.17) all fail to enter. The price-side null outside FG likewise holds for every asset in Panel B of Table 4.1.

1.26 8.4 Pipeline audit

Every headline number runs through the archival pipeline: the shock file (single CSV, versioned), the dataset builder with sanity checks (statement length, tone–length correlation, CRSP same-day cross-checks), and per-chapter result JSONs committed to the repository. Statement scores carry a five-layer audit (Appendix A) with per-statement verdicts; the two drafting-stage corrections (Operation Twist's router one-off; retirement of two untraceable recalled numbers) are documented in the audit notes rather than silently fixed. # 9. Conclusion

We asked how Federal Reserve communication reaches asset prices and household portfolios, and answered with an identification — the market's inversion rule — rather than a new text score. The answer has three parts. On the announcement day, both the conventional and the information components of policy news move prices with the Jarociński-Karadi sign structure, and the statement's tone carries incremental price information precisely in the forward-guidance era — hawks lift yields and sink valuations at once, and the text survives a horse race against both shocks. Monthly flows ignore the words entirely: the null holds for the shocks, for tone, and for an audited LLM measure, at every window we can construct. What flows do respond to is the *risk content* of the information — a de-risking ladder on hawkish information, sign-asymmetric, with a zero-rate-regime exception that reveals the conventional channel operating through rescue capacity.

For the communication-paradigm literature, the measurement chapter delivers a caution with teeth: the dictionary does not mis-read paradigm-shift statements, it fails to differentiate them (65× resolution loss on the eleven episodes that define the shifts), so dictionary-based tone findings on exactly those episodes are under-identified. The LLM-based diagnostic — audited, cross-vendor confirmed, and positioned as a measurement tool rather than a competitor — is the repair we offer.

Limitations. Flow aggregation is monthly and class-level; the window structure, however carefully bounded, cannot separate intra-month timing. The text measures cover statements only — minutes and speeches are outside scope. The LLM layer inherits vendor dependence; the committee rule and the audit protocol bound, but do not eliminate, that dependence.

Policy reading. If prices clear the words and portfolios follow the risk, then central-bank communication works on household portfolios *through repricing*, not through persuasion — and communication regimes that shift the paradigm (forward guidance, structural operations) are precisely where text-measurement tools must be re-validated before their scores are interpreted.
